ABSTRACT

Large organizations today operate data centers around the globe where massive amounts of data are produced and consumed by local users. Despite their geographically diverse origin, such data must be analyzed/mined as a whole. We call the problem of supporting rich DAGs of computation across geographically distributed data *Wide-Area Big-Data (WABD)*. To the best of our knowledge, WABD is not supported by currently deployed systems nor sufficiently studied in literature; it is addressed today by continuously copying raw data to a central location for analysis. We observe from production workloads that WABD is important for large organizations, and that centralized solutions incur *substantial cross-data center network costs*. We argue that these trends will only worsen as the gap between data volumes and transoceanic bandwidth widens. Further, emerging concerns over data sovereignty and privacy may trigger government regulations that can threaten the very viability of centralized solutions.

To address WABD we propose WANalytics, a system that pushes computation to edge data centers, automatically optimizing workflow execution plans and replicating data when needed. Our Hadoop-based prototype delivers 257× reduction in WAN bandwidth on a production workload from Microsoft. We round out our evaluation by also demonstrating substantial gains for three standard benchmarks: TPC-CH, Berkeley Big Data, and BigBench.

1. INTRODUCTION

Many large organizations today have a planetary-scale footprint and operate tens of data centers around the globe. Local data centers ensure low-latency access to users, availability, and regulatory compliance. Massive amounts of data are produced in each data center by logging interactions with users, monitoring compute infrastructures, and tracking business-critical functions. Analyzing all such data globally in a consistent and unified manner provides invaluable insight. We refer to the problem of supporting arbitrary DAGs of computation over data born in geographically distributed data centers as ***Wide-Area Big Data (WABD)***, and argue for solutions that are *cross-data center bandwidth conscious*.

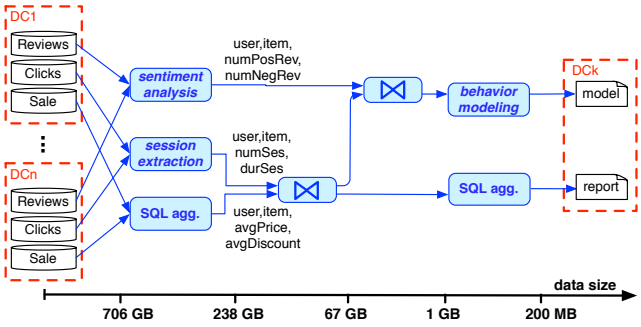

Figure 1: Running example

We introduce WABD using the running example in Figure 1. This example, derived from BigBench [21], is representative of the data processing needs we observe in Microsoft production workloads. It is also consistent with data processing pipelines at Yahoo! [20], Facebook [38], Twitter [29], and LinkedIn [12]. Figure 1 shows three input data sources: `clickstream`, storing Web server logs of user browsing activities; `reviews`, capturing textual representations of item reviews; and `sales`, a relational table storing transactional records of item purchases. Unlike parallel databases and Big Data systems, the data is distributed across "nodes" (i.e., data centers) to reduce latency of Web server interactions and not to scale-out the analytical framework. As a result, we have *no control on the base data partitioning*: data is born distributed; we only control data replication and distributed execution strategies. The DAG of operators shown in Figure 1 depicts one of the many workflows run daily to process the raw data and extract insight about user behavior, sales performance, and item reception. In particular, beside classical relational operators, this workflow includes *arbitrary computations* that manipulate unstructured data (`session extraction` and `sentiment analysis`) and machine learning stages (`behavior modeling`).

The practical relevance of data analysis like this one can be seen in the dozens of single- and multi-machine relational OnLine Analytical Processing (OLAP) systems [6, 7, 4, 10, 14], and more recently with the development of massively scalable data processing frameworks [36, 39, 3, 40, 34], collectively referred to here as Big Data systems. All these

7th Biennial Conference on Innovative Data Systems Research (CIDR '15) January 4-7, 2015, Asilomar, California, USA..

systems provide sophisticated *single-cluster* analytics solutions. Recent efforts [23] have focused on data replication for disaster recovery, but their analytics components still operate on a single data center. We discuss the vast related work in distributed databases and workflow management systems in §4.

Companies deal with WABD today by copying remotely-born data to a central location for analysis. Throughout the paper we will refer to this as the *centralized* solution. Any such solution is destined to consume cross-data center bandwidth proportional to the volume of updates/growth of the base data. Referring back to Figure 1, this consists of copying the partitions for the three base data sources `click-stream`, `reviews`, and `sales`, from the edge data centers to a central location, and running the DAG leveraging standard single-cluster technologies. For example, using a Hadoop stack, one could use *DistCP* to copy data across HDFS instances in each data center, *Oozie* to orchestrate the workflow, *Hive* for relational processing, *MapReduce* for session extraction, *OpenNLP* for sentiment analysis, and *Mahout* for behavior modeling. We prototyped this setup and gathered initial numbers to quantify the cost of this approach. Assuming daily runs of the DAG of Figure 1, 1 TB daily data growth, and 10 data centers, we observe cross data center traffic of 706 GB per day. (Other base data sources in the original benchmark, not used by the DAG in Figure 1, make up another 318 GB per day.)

The distributed solution we propose significantly reduces this bandwidth cost. Further, we argue that any centralized solution is *on a collision course with current technological and geo-political trends*: 1) data is growing much faster than cross-data center bandwidth, and 2) growing privacy and data sovereignty concerns are likely to result in government regulation that threatens the viability of centralized approaches (e.g., German-born data might not be stored in US data centers). The table below summarizes how WABD differs from classical database problems.

WABD Problem: Novel dimensions	
Data Placement	No control on data partitioning (only on replication)
Target Computation	Arbitrary DAGs (vs relational)
Optimization Metrics	Cross-data center bandwidth (abundant CPU/Storage)
New Constraints	Data sovereignty + Heterogeneous bandwidth

To address the challenges of WABD, we build **WANalytics**, a system that supports arbitrary DAGs of computation on geographically distributed data. WANalytics automatically devises distributed execution plans and an accompanying data replication strategy. These two aspects are addressed concurrently to minimize WAN bandwidth utilization while respecting regulatory requirements. In designing WANalytics we make three contributions:

1. We introduce a caching mechanism akin (for networking) to *syntactic* view maintenance for arbitrary computations.
2. We explore the joint space of distributed execution plans and data replication strategies, and propose a greedy heuristic, and show its limitations.
3. We propose "pseudo-distributed measurement", a technique that circumvents cardinality estimation by running user queries *as if* they were distributed and measuring their actual cost.

WANalytics vastly outperforms the centralized approach, moving only 1.07 GB across data centers when tasked with the DAG of our running example. We obtain similar results (over 250× bandwidth reduction) on a large production workload from Microsoft, on TPC-CH [16], and BigBench [21] benchmarks, and show more modest gains for the Berkeley Big Data Benchmark [13] (§3).

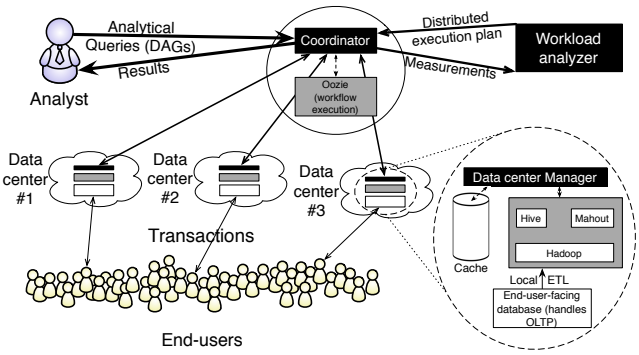

Figure 2: WANalytics architecture

We conclude by discussing how WANalytics can serve as a starting point to address data sovereignty concerns, and by listing several open questions regarding approximate query answering, differential privacy, query optimization, view selection and incremental maintenance for the emerging problem of Wide-Area Big Data.

2. WANalytics OVERVIEW

WANalytics pushes computation to edge data centers, and replicates the base data when needed, while respecting data sovereignty constraints. We describe the architecture, the components, and two new techniques (pseudo-distributed measurement and syntactic view maintenance) that underly our system.

2.1 Architecture

WANalytics consists of two main components (see Figure 2): (1) a *runtime layer* that executes user DAGs in a distributed way across data centers, moving data according to the execution and data replication strategies devised by (2) a *workload analyzer* that continuously monitors and optimizes the user workload.

Runtime layer comprises a centralized *coordinator* in a master data center that interacts with *data center managers* at each edge data center. Users submit logical DAGs of computation (such as the one in Figure 1) to the coordinator. The coordinator in turn asks the workload analyzer to provide a *physical distributed execution plan* for a given DAG. The physical plan explicitly specifies where each stage is going to be executed, and how data will be transferred across data centers. We leverage Apache Oozie [1] to handle the mechanics of orchestrating distributed execution, and simple faults, while we provide purpose-built components to collect statistics on job execution and base data growth (e.g., volume of updates on the base data). By design our system can support DAG operators expressed in any framework compatible with Oozie (e.g., Hive, Pig, MapReduce, Spark). After execution completes, job statistics from each data center manager are sent to the workload analyzer to aid future query optimization. As part of our runtime layer we developed a data transfer optimization that minimizes the redundancy of subsequent transfers (§2.2).

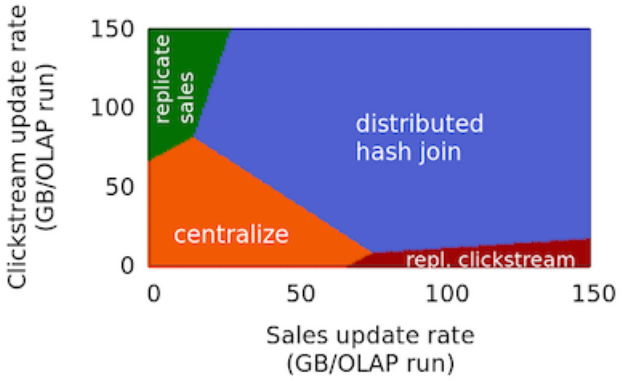

Figure 3: Optimal strategy for `session extraction` ⋈ `sales summarization`

Workload analyzer WANalytics is targeted towards applications with a slowly-evolving core of recurring jobs (DAGs) that make up the bulk of the workload. This is a reasonable assumption in the context of WABD, as we confirm by inspecting several production workloads at Microsoft. The *workload analyzer* jointly optimizes all the DAG execution plans of the workload, along with the data replication policy. The resulting search space is inherently vast, and we thus propose a greedy heuristic to explore it efficiently in §2.3. During this optimization step the system translates the logical input DAGs into fully qualified distributed physical plans. We take a two-step approach, in which we first generate an optimized centralized plan and then add distribution to it, as often done in the past [27]. We handle conservatively all operators with unknown semantics/requirements, i.e., we assume they can only be run in a single data center on local data. As an example consider the machine learning step of `behavior modeling` in our running example. On the other hand, we leverage the known semantics of relational operators and MapReduce jobs when possible. For example we detect that the `sentiment analysis` stage in our running example is a map-only job, and we can thus "push-down" its execution to each edge data center. Figure 4 shows the results of this optimization for our running example.

The analyzer *costs* each alternative execution by means of the technique we discuss in §2.4. The workload analyzer also establishes a policy for base data replication, i.e., it decides whether for each base data source it is worthwhile to maintain a replica in another data center to reduce network transfers.

The workload analyzer is run every *epoch* (e.g., once a day). This allows us to continuously assess the performance of current strategies and investigate alternative options. The goal is to progressively improve upon the current strategies by carefully exploring the space. Each change of strategy is carefully vetted (§2.4), and we favor robust plans, since the cost of mistakes in our environment is very high.

We next discuss: an optimization we deploy to reduce the cost of data transfer (§2.2); the algorithm used by our prototype of the workload analyzer (§2.3); and the technique we use to make it possible to cost alternative execution strategies (§2.4).

2.2 Data transfer optimization

The unique setting we consider, in which each "node" is a full data center with virtually limitless CPU and storage capabilities, and connectivity among nodes is very costly/limited, lends itself to a novel optimization. We cache all intermediate results generated during DAG execution at each data center, and systematically compute diffs[1] to reduce cross-data center bandwidth. Whenever a source data center S sends the result for a computation C to a destination data center D, both S and D store a copy of the result of C in a cache tagged with $\langle \text{signature}(C) \rangle$[2]. The next time S needs to send results for C to D, it evaluates C again, but instead of sending the result afresh, it computes a diff between the old and new result, and sends the smaller between the diff and new result. D then applies the diff onto its copy of the old result.

In many cases a change in the base data affects only part of the output of C, hence a significant data transfer benefit can be obtained by our data transfer optimization. Our approach is agnostic of what C does, but systematically removes redundant data transfers, by detecting overlap. This is done at the cost of increased computation and storage requirements on each data center (to cache data and compute diffs).

Interestingly, this form of caching helps not only when end-users submit the same DAG repeatedly, but also by eliminating redundant transfers *across* DAGs sharing common sub-computations. In the TPC-CH benchmark, 6 different DAGs all compute slightly different aggregates on top of the same (relatively data-intensive) join. Caching reduces the data transfer for these DAGs by 5.99×.

In a sense, our data transfer optimization is a *syntactic* form of view maintenance for arbitrary computations. We materialize an implicit view the first time a computation arrives, and lazily refresh it at every subsequent query that overlaps this. The purely syntactic nature of this process allows it to function for arbitrary computation. However, compared to classical relational view maintenance mechanisms, our cache is likely to waste computation/storage, and possibly miss opportunities for optimization.

2.3 Workload analyzer

The workload analyzer takes as input a set of logical DAGs and the base data natural partitioning. It then determines the combination of choices for the following three factors that would minimize total bandwidth usage: (1) the physical operator to use for tasks that accept multiple implementations (e.g., hash, broadcast or semi join), (2) the data center where each task is executed (respecting sovereignty constraints), and (3) the set of data centers to which each partition of the base data is replicated. These decisions are difficult for several reasons.

First, finding the best execution strategy for each task in a DAG in isolation, is by itself non-trivial. For example, the choice of optimal join execution strategy is a complicated function of several parameters: the sizes of the base tables, the rates at which they are updated, the selectivities of each of the task in the DAG, etc. Figure 3 shows the best join strategy for the join between the output of the `session ex-`

[1]Diffs are computed at the record level, if the record format is known, or on the binary representation otherwise.

[2]signature(C) = depth-first traversal of the sub-DAG induced by C. This mechanism is imperfect – e.g. changing the order in which DAG edges are listed can change the signature and cause a cache miss – but is a reasonable starting point.

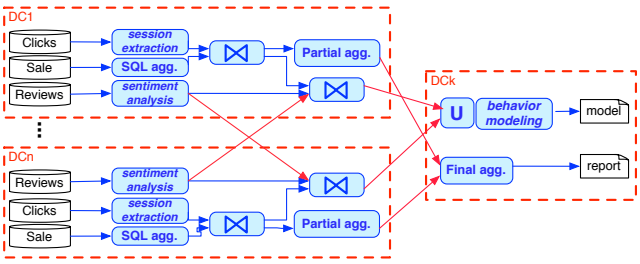

Figure 4: Placement of the running example DAG

`traction` and `sales summarization` tasks from Figure 1, as a function of the rate at which the `sales` and the `clickstream` tables are updated. Depending on the update rates of the base tables, one of the following strategies dominates: copying both tables centrally, broadcasting the updates of the least modified table, or performing a distributed hash join (i.e., re-distributed both tables via hashing). Second, the choice of execution strategy for a DAG node may affect the choice of strategies for other DAG nodes, as this choice determines the partitioning and placement of the node's output data. In a workload with n nodes (in one or more DAGs) and up to k possible execution strategies per node, the analyzer would have to explore a $O(k^n)$ search space. Third, the choices made for nodes of different DAGs influence each other, as they might leverage a shared data replication strategy, or be affected by the optimization discussed in §2.2. Hence, we propose a *Greedy Heuristic* that performs remarkably well in practice, while exploring only a small subset of the search space.

Algorithm 1 Greedy Heuristic

```
for all DAG G ∈ workload do
    for all task t ∈ toposort(G) do
        t.completed = false
        if ∃ parent p of t such that p.completed = false then
            assign a default strategy to t
        else
            if all strategies for t have been evaluated then
                for all data source S ∈ input(t) do
                    test if replicating S reduces bandwidth further
                assign the lowest cost strategy to t, and replication
strategy to S
                t.completed = true
            else
                explore next strategy for t
```

Greedy Heuristic The heuristic (Algorithm 1) optimizes each node of each DAG in isolation, proceeding from the source nodes and moving greedily outward in topological order. For each node, we evaluate all strategies compatible with sovereignty constraints, using pseudo-distributed measurement (§2.4) to measure their costs, and greedily pick the lowest cost alternative at that node. In the process, the system also evaluates whether systematically replicating any of the input base tables can help amortize transfer costs among DAGs.

Figure 4 shows the resulting execution strategy for the DAG in our running example. The arrows in *red* are cross-data center data transfers, and add up to 1.07 GB. Most of the cost is incurred while broadcasting the output of sentiment analysis during join computation. The alternatives–such as using a semi-join, or redistributing via hashing—all turn out to be more expensive. In our running example,

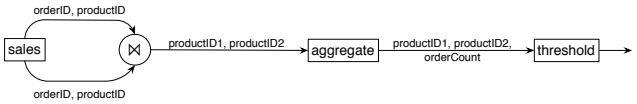

Figure 5: Example where heuristic fails

WANalytics decides not to replicate base tables, but replication proves fundamental for all workloads in our experiments (§3).

This simple heuristic requires a limited number of measurements (as it explores just a small portion of the search space), and experimentally works well whenever DAGs "reduce" data volumes at each subsequent stage. This seems common in practice: it is true of 98% of all the DAGs in our workloads.

Limitations This heuristic can fail when confronted with DAGs that "expand" the input data they consume (before optionally condensing it). Consider the DAG in Figure 5, a simplified version of query *Q1* in the BigBench benchmark. The DAG starts from a table listing items ordered by customers (size n), performs a self-join on the table to find pairs of items that are ordered together (worst case size $O(n^2)$), computes frequencies of pairs, and returns frequent pairs. The heuristic would push the join down and run it distributed, thus exploding data in edge data centers, incurring unnecessarily large data transfer during the second stage.

We are actively working on a non-linear integer programming (NLIP) model that can explore the search space more systematically. We currently have a limited IP formulation for the special cases when either all nodes in the DAG are SQL operators or all the nodes are MapReduce operations — it turns out that this formulation does identify the correct strategy in this example. However, at the time of this writing, the arbitrary DAGs we allow in our system are beyond our reach.

2.4 Pseudo-distributed measurement

Like most optimizers, our workload analyzer must *cost* each strategy it considers. Traditional cardinality estimation techniques, based on data statistics and histograms, are insufficient for the arbitrary computations we target. We propose *pseudo-distributed measurement*, a mechanism that allows us to "measure" the cost of running a DAG *as if* it was executed according to a different strategy.

Consider the DAG in Figure 1, and assume the system is currently deployed in a centralized manner (i.e., all data are replicated centrally), but we want to explore the cost of a distributed execution (e.g., one in which `session extraction` is run on each data center). The analyzer would need to estimate data volumes produced by each operator when run on the portion of the input data stored at each data center. This information is not directly available when the query is run centralized (as input data are combined during operator execution and their provenance is lost).

To estimate data sizes when multiple (input or intermediate) data partitions are housed in a single physical data center, WANalytics simulates a virtual data center topology in which each partition of input data is in a separate data center. This is done by decomposing an operator O in the DAG into multiple sub-operators O_i, each executing on a portion of the data and a final stage O_c combining their

results – this is done only for operators whose semantics is compatible with such decomposition. We enrich the data with a "provenance" field that tracks the data centers where they were born. This allows O_i to filter the data and run only on data coming from data center i. We then measure the size of each O_i output and infer the cost of running O distributed. In the `session extraction` example, WANalytics would create [# of DCs] separate tasks that operate on each partition of the `clickstream` dataset separately, computing session statistics for each user at each data center, followed by a simulated data transfer to a virtual central node that computes the final aggregate session statistics for each user.

Pseudo-distributed measurement *does* affect execution performance (up to 20% in our experiments). This can be mitigated by increasing parallelism of execution in most cases (not our focus here). Most importantly, each measurement runs within a single data center, thus never increases the volume of data transferred *between* data centers. We omit the details of how the measurements are executed when the execution plan is already distributed.

To summarize, pseudo-distributed measurement consists of a costly but very accurate measurement of the execution costs under different execution strategies, achieved by means of DAG rewriting and actual execution.

Limitations To explore all options considered by the heuristics of Section 2.3, WANalytics has two options: (1) run a different pseudo-distributed measurement every time the DAG is submitted by the user, or (2) run dedicated jobs that have the sole purpose of costing different options. In either case, if d is the longest path of any of the DAGs in the workload, and k the maximum number of strategies available for any task, we might require up to $k*d$ epochs/submissions to collect all needed measurements.

This could be slow in certain settings, and indicates that hybrid solutions, combining the low-cost of classical cardinality estimation using statistics/histograms with the high-precision of pseudo-distributed measurement, are likely needed.

3. EXPERIMENTAL EVALUATION

In this section, we compare WANalytics with a centralized deployment over various workloads.

3.1 Workloads and Experimental Setup

Microsoft production workload: This use case consists of a monitoring infrastructure collecting tens of TBs of service health/telemetry data daily at geographically distributed data centers. The data are continuously replicated to a central location, and analyzed by means of a mix of purpose-built near-real time analysis and Hive-based batch analytics. The bulk of the load is produced by few tens of canned DAGs producing aggregate reports on service utilization and infrastructure health, and by thousands of ad-hoc analytical queries (submitted over a 6 month period of time by the engineering team for triaging/testing purposes). The complexity of the DAGs ranges from small to medium (up to tens of stages).

BigBench: This workload [21] has been recently proposed as a first step towards a SPEC standardization. It comprises a relational portion, TPC-DS, and the two non-relational sources we show in our running example, `clickstream` and `reviews`. In our multi-data center setup, we assume data are produced at edge data centers, and that accesses by the same user are logged in one location. This reasonable assumption of co-location lowers the cost of joins, but is *not* required for WANalytics to work correctly.

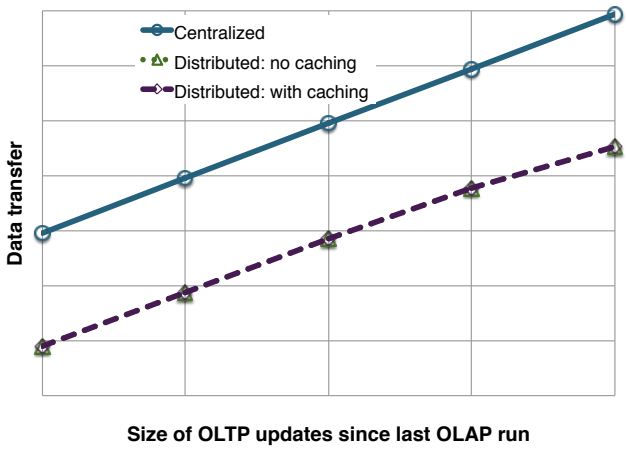

Figure 6: WANalytics vs centralized baseline on Microsoft production workload

TPC-CH: The TPC-CH benchmark [16] models the database for a large-scale product retailer such as Amazon, and is a joint OLTP/OLAP benchmark, constructed by combining the well-known TPC-C OLTP benchmark with the TPC-H OLAP benchmark. In our experiments, we assume that the TPC-C portion of the workload is exercised locally at each edge data center, while the TPC-H analytics are meant to be run on the overall data.

Berkeley BigData Benchmark: This benchmark [13], developed by the AMPLab at UC Berkeley, models a database generated from HTTP server logs[3]. Once again we assume that the raw data are logged by web servers at edge data centers.

Experimental setup. We ran our experiments across three geographically distributed Azure data centers (US, EU, Asia), and on a large on-premise cluster, on which we simulate a multi-data center setup. Specifically, we ran the benchmark-based experiments in both deployments for up to 25 GB of data transfers. Experiments on the larger Microsoft workload and on benchmarks in the 25 GB to 10 TB range have been conducted exclusively on the on-premise cluster. This is because each of the multi-terabyte runs for the baseline centralized approach would have otherwise cost thousands of dollars in cross-data center bandwidth. The on-premise cluster consists of 120 machines, each with 128 GB of RAM, 32 cores, and 12 x 3 TB of drives. The interconnect is 10 Gbps within a rack, and 6 Gbps across any two machines.

3.2 Comparing WANalytics with Centralized

The software stack we use in these experiments is based on a combination of Oozie, Hive, MapReduce, OpenNLP, Mahout and DistCP. Since our focus is on network bandwidth consumption and not query execution performance, we expect similar results from alternative choices of stack. All

[3]This benchmark has queries that are parametric. We set the parameter to the median value of 0.5 for this experiments.

network transfers, both baseline and WANalytics, are gzip-compressed. For the centralized baseline we always pick the best between log-shipping and batch-copying.

Figure 6 shows the results of running WANalytics and the centralized baseline on the Microsoft workload (axes hidden due to proprietary nature of the data). Figure 7 shows an equivalent set of experiments for the three standard benchmarks we consider. On the y-axis we report the cross-data center network bandwidth consumed by each approach, for different volumes of update/growth of the base data between runs of the analytical workload. This is consistent with our observation of production workloads, where analysis is run on a fix daily schedule, while the raw volume of data growth/update changes with the service popularity (in this case, growing aggressively over time). Our workload analyzer consistently picks the lowest among centralized and distributed solutions from Figures 6, 7. To avoid crowding the figures, we omit these lines. The key insights from these experiments are:

1. The **centralized approach grows linearly** with raw data updates/growth. Note that slope is < 1 due to compression.
2. **Controlling base-table replication is key** to lower bandwidth consumption for frequently-read, rarely-updated tables (e.g., dimension tables in TPC-CH).
3. **At low update rates, centralized outperforms distributed for two of the four workloads**. This is because frequent analytics operate on mostly unchanged data.
4. **At high update rates distributed outperforms centralized by 3× to 360×**. The larger advantages accrue for workloads where we can push operators to edge data centers more effectively. The Berkeley Big-Data Benchmark results are dominated by a single query, which requires to move large amounts of data to compute a top-k.
5. **At low/medium update rates caching is effective**. This is due to the large redundancy among the answers to subsequent runs of overlapping queries. By contrast, at high-update rates, and for queries with no overlap (Fig. 6) caching is not effective, since transfer redundancy is already minimal.

Overall, these results are very encouraging, and confirm a substantial opportunity to address WABD by means of distributed execution of complex DAGs.

4. RELATED WORK

Distributed databases Although analytical query processing has been extensively studied in the database literature [14], few papers have considered a wide area distributed setting such as ours. Distributed query processing was surveyed in [27] with a focus mostly on join processing. The optimization of queries with aggregations is presented in [10]. Recently, [18, 28] focused on geo-replication for OLTP workloads. PNUTS/Sherpa [17] supports geograhically distributed partitions, laying out data to optimize latency (by moving a "master" copy close to where it is commonly used). Mesa [23] focused on geo-replicated data warehousing, whereas Riak [5] also provides multi-datacenter replication. WANalytics differs from these approaches, as it focuses on arbitrary DAGs, and it supports geo-*distributed* execution of DAGs of computation.

Single-cluster scale-out platforms Shared-nothing parallel databases, such as Netezza [6], Vertica [7] and Greenplum [4], began as a means to accommodate ever-increasing data in data warehouses. More recently, other flavors of scale-out systems have emerged with systems like Hive [36], Impala [3], Shark [39] and SciDB [37]. Unlike our setting, all these scale-out solutions control partitioning and are deployed in single clusters. In fact, our work is complementary: WANalytics could leverage these systems as building blocks.

Workflow management systems Recently, various systems for richer workflow management have been proposed, e.g., Pig [34], Spark [40], Oozie [1], Storm [2]. These systems are typically not geo-distributed and lack a sophisticated optimizer. Conversely, the need for distribution was identified early on in scientific workflow systems [11]. Pegasus [19] is a representative example, which tailors the execution of an abstract DAG to a specific Grid environment. Although relevant, Pegasus does not consider data replication during placement of tasks.

Query optimization Many works have considered query optimization in distributed databases [27]. R* [31] was among the first to add distribution to the traditional dynamic programming optimization algorithm. Similar to our work, many systems reduce the complexity of optimization using a two-step centralized-to-distributed optimization [27]. Recent work on multi-query optimization [22] also relates to our multi-DAG approach. RoPE [8] and DynO [26] gather runtime data statistics, but do not change the computation to facilitate extra measurements. Babu et al. systematically addressed the optimization of MapReduce workflows [30, 24]. Their approach can be used to optimize our initial centralized plan, but does not consider our geo-distributed scenario. Overall, optimizing arbitrary DAGs remains a hard problem; no previous work has sufficiently addressed the mix of constraints and network-focus of WABD.

Data replication Most research in distributed databases focuses on static techniques for data replication [27]. Moreover, the problems of query optimization and data replication are tackled independently despite being interrelated. On the contrary, in WANalytics, we tackle both problems at once. Data placement in the context of Pegasus was studied in [15], assuming prior knowledge of the workflows and placing replicas asynchronously before execution.

Other architectures Sensor networks share our assumption of expensive network bandwidth with respect to compute/storage [32]. The obvious differences in scale (one micro-controller vs. one data center), and the much broader computation model we assume, make most techniques from this space not directly applicable, though relevant as an inspiration. Likewise, stream-processing databases [25, 2] consider a more restrictive model than ours, in which data are always produced at edge nodes and are not replicated. Work in the CDN setting [35] has begun to address geo-distributed analytics, but with much simpler data models.

5. CONCLUSION AND OPEN PROBLEMS

The recent explosion of data volumes has reignited the focus on scale-out data analytics, and has fostered the world of Big Data systems. While these paradigms suffice for a single data center, we believe we have reached a new inflection point where the combination of big and geographically distributed data requires new approaches for geo-distributed analytics processing to minimize wide-area bandwidth costs. Centralized approaches together with heuristics such as data reduction or ad-hoc distributed querying may suffice in the short term. However, they are not sustainable as data volumes grow relative to transoceanic bandwidth and regulatory concerns become paramount.

In this paper we presented an architecture for solving the Wide-Area Big Data problem. We showcase the unique features of this problem, and introduce new techniques to cope with it. Our prototype implementation, WANalytics, achieves over 250× bandwidth reduction in a Microsoft production workload, and significant gains for a range of standard benchmarks. Besides presenting an initial proposal, we hope our paper serves as a problem statement and a call to arms. Many challenges remain open including:

Improved workload optimization The optimization problem we tackle is challenging, combining distributed (multi-)query optimization and data replication. The proposed heuristic only scratches the surface and much needs to be done in this space. Adapting recent advances on view selection and maintenance, as well as cardinality estimation, to our more-than-relational, geo-distributed setting is an interesting avenue.

Approximate query answering lends itself well to build bandwidth-conscious WABD solutions, where trading precision for network costs is very appealing [9].

Fault tolerance / Consistency / Latency are not addressed here, but are clearly needed to make WABD a reality; coordinating replication for disaster recovery and query answering is also intriguing.

Privacy WANalytics respects raw data storage requirements, but does not limit data moved by queries. This suffices for scenarios where all queries are vetted before they can be executed, but automated solutions incorporating differential privacy techniques [33] would be interesting to explore.

In conclusion, WABD is a new spin on classic database problems that is growing in relevance. While it can benefit from existing techniques, significant novel research will be needed.
